Mara Zimmerman

Background

- Since 1915 Columbia River fisheries have been regulated by the Columbia River Compact (States of OR & WA)
- Commercial harvest of Columbia River steelhead prohibited by WA in ~1930's and by OR in 1970's
- Purse, horse, hand, and beach seines were prohibited by OR & WA between 1922 and 1948
- Seine use was terminated due to user conflict

Policy Direction

- In 2012 a petition to eliminate gill nets from Columbia River was drafted as a ballot measure in OR
- Gov. Kitzhaber proposed a plan to phase out gill nets in the mainstem Columbia River in response to ballot measure.
- WDFW & ODFW Commissions adopted policies in this direction
- Seines were considered as an alternative to gill nets
- Pursue studies to estimate survival of salmon and steelhead released from seines

Project Goals

- Estimate post-release survival of salmon and steelhead released from purse and beach seines:
 - Short-term survival is from the seine fishery (above Washougal River) to Bonneville Dam (BON) (~15km)
 - Intermediate-term survival is from BON to McNary Dam (MCN) (240km) includes fisheries and tributary PIT tag detections (e.g. Deschutes, John Day, Klickitat, etc.)
 - Cumulative survival is from the seine fishery to MCN including tributary and fisheries detections
- Assess covariates in predicting post-release survival of salmon & steelhead caught and released from seines

Experimental Seine Fishery

- Experimental seine fishery occurs in the fall (Aug-Oct) & targets Chinook and coho salmon
- Fishery was monitored from 2011-13 and each vessel had an observer and all caught fish were tagged with Passive Integrated Transponder (PIT) tags
- Mean salmon and steelhead catch per set was 11 and 1 fish, respectively
- Mean daily water temperature was 19.5°C (range 14.1 – 22.4 °C)
- Recover PIT tags through out the Columbia River including BON, MCN, tributary PIT tag interrogation sites and fishery sampling

Purse Seine fishery

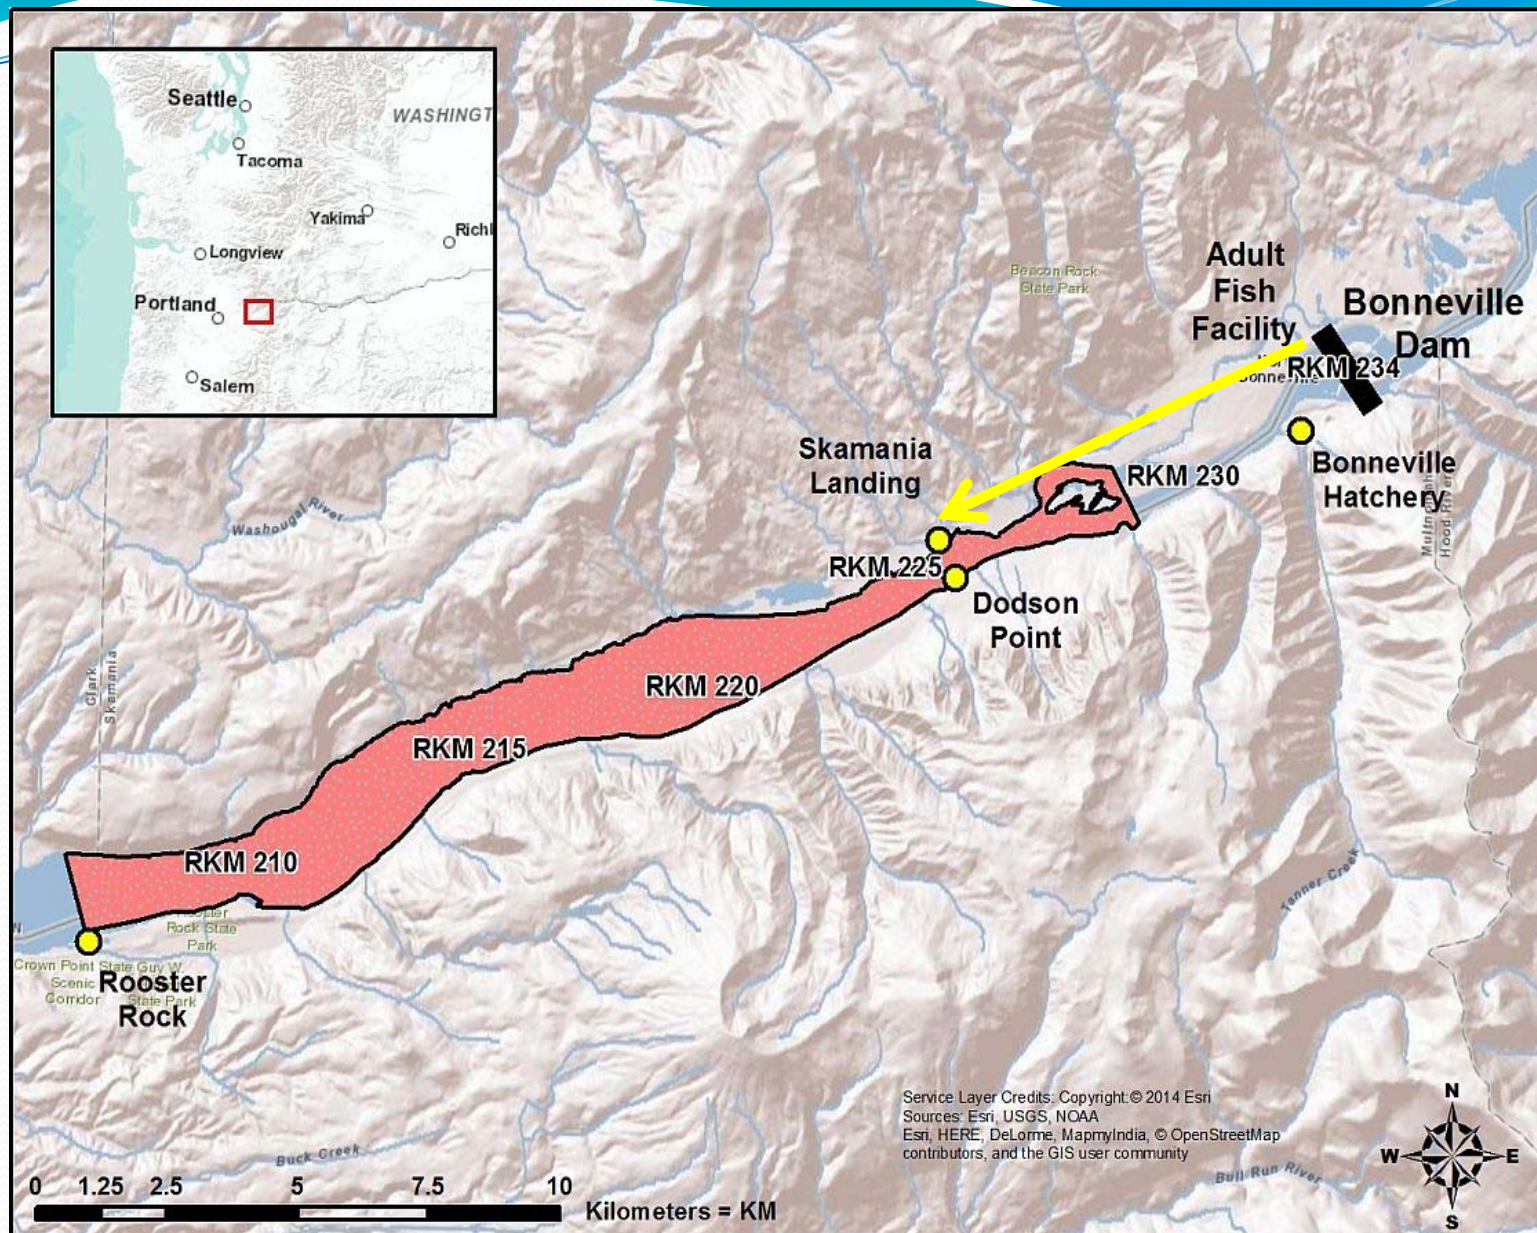

- Seine length ranged from 150 - 250 fathoms or 274-457 meters
- Seine depth is variable but generally > 12 meters
- Mesh size 8.9cm with purse seines having a 2.5cm bunt
- Set time (first cork out until last fish removed) for purse seines (mean = 71 minutes)

Beach Seine Fishery

- Same seine as purse seines except no bunt
- Set time less than purse seines (mean = 44 minutes)

Ricker-Two-Release Study Design

- T = # C & R in fishery by seines (Treatment Group)
- C = # C & R @ BON released < BON (Control Group)
- t = # of Treatment Group captured at BON
- c = # of Control Group captured at BON
- $\phi = \frac{t/T}{c/C} = \frac{\rho_t}{\rho_c}$
- Survival estimate is the recapture of treatment relative to controls

Ricker-Two-Release Design

- Previous slide was short-term survival (fishery to BON)
- Same design was repeated for control and treatment fish detected at BON to estimate intermediate-term survival (BON to MCN including fisheries and tributaries)
- Cumulative survival is the product of short-term and intermediate survival
- Key assumption is the control & treatment group are from the same population (e.g. they have the same proportion of individuals that originated above Bonneville Dam)

Results

- Tagged 1990 adults steelhead caught in seines and tagged 950 controls with PIT tags over 3 years.
- Immediate survival = 99.7%
- Short-term survival = 96%
- Intermediate survival = 100%
- Cumulative survival = 96%

Short-term Survival

Intermediate-term Survival

Cumulative Survival

Alternate Short-term Survival Estimate

- Probability of capture for treatment group: $p=t/T$
- Adjust the observed PIT tag detection at BON to obtain an unbiased estimates based on:
 - PIT tag detection at BON
 - PIT tag retention, and
 - Tagging induced mortality

Short-term Survival

solid line=Ricker-Two-Release
dashed line = Alternate Method

Why was survival so high (>96%)?

- Logistic regression to examine possible explanatory covariates (water temperature, date, flow, length, and origin) for treatment and controls
- Log linear models to examine fish condition

Logistic regression

- Best model was the null or intercept only model which indicates that the covariates explained little of the variation in the detection of control or treatment fish.
- Mean daily water temperature was 19.5°C (range $14.1 - 22.4^{\circ}\text{C}$)
- Median temperature for the date of peak steelhead passage at BON for the last two decades was 21 degrees (Figure on right)
- Suggests local adaptation of Columbia River steelhead to warm water temperatures

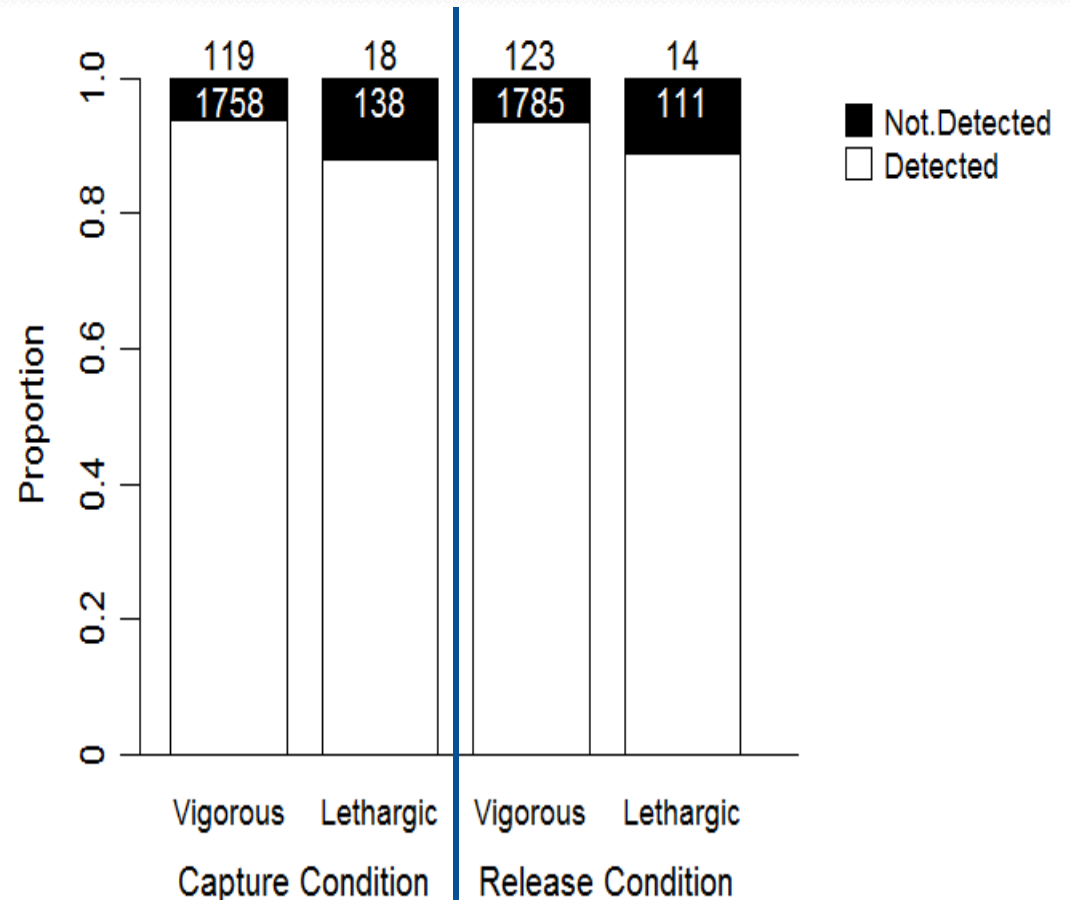

Fish Condition(1)

- 96% of the fish are not injured; exhibit no physical signs of being caught in a net
- High detection for non-injured & tangled fish (94% & 90%) but low (62%) for wedged/gilled
- Previous studies have indicated wedged/gilled are the most seriously injured fish and have lower survival rates

Fish Condition(2)

- Fish were classified as lethargic or vigorous upon recapture and release
- 92% & 94% were classified as vigorous at capture and release
- 94% of fish classified as vigorous at release were detected compared to 88% of fish classified as lethargic

Summary

- Cumulative survival was ~96% for steelhead released from seines
 - Almost all mortality (4%) was short-term (fishery to BON, 15km, 2.7 days)
- High steelhead survival in the study is likely due to a variety of factors
 - Steelhead caught in seines were in good condition
 - 96% were not injured
 - 94% were vigorous on release
 - Catch was low and averaged 11 salmon and 1 steelhead per set
 - Fish were in gear for a short amount of time; 71 and 44 minutes per set for purse and beach seines
 - Seiners typically use a brail to hoist fish from the water to the deck, which causes mortality through crushing especially when catch is high
 - Since steelhead were individually netted from the seine in this study, there was no mortality due to crushing
